The filtered density function (FDF) closure is extended to a “self-contained” format to include the subgrid-scale (SGS) statistics of all of the hydro-thermo-chemical variables in turbulent flows. These are the thermodynamic pressure, the specific internal energy, the velocity vector, and the composition field. In this format, the model is comprehensive and facilitates large-eddy simulation (LES) of flows at both low and high compressibility levels. A transport equation is developed for the joint pressure-energy-velocity-composition filtered mass density function (PEVC-FMDF). In this equation, the effect of convection appears in closed form. The coupling of the hydrodynamics and thermochemistry is modeled via a set of stochastic differential equation for each of the transport variables. This yields a self-contained SGS closure. For demonstration, LES is conducted of a turbulent shear flow with transport of a passive scalar. The consistency of the PEVC-FMDF formulation is established, and its overall predictive capability is appraised via comparison with direct numerical simulation (DNS) data.

DOI: 10.1103/PhysRevFluids.2.094603

I. INTRODUCTION

The filtered density function (FDF) and its density-weighted filtered mass density function (FMDF) have proven very effective for large-eddy simulation (LES) of turbulent flows [1–8]. The most sophisticated form of the model to date is one accounting for the joint frequency-velocity-scalar subgrid-scale (SGS) statistics (FVS-FMDF) [9], and a simpler version (VS-FMDF) which does not include the SGS frequency [10–12]. Inclusion of entropy and irreversibility is reported in Refs. [13–15], and extension to multiphase flows in Refs. [16,17]. Hydrodynamic closure in incompressible, nonreacting flows has been achieved via the marginal velocity-FDF (V-FDF) [18], and the FDF which considers only the species mass fraction field is the scalar FDF (S-FDF and S-FMDF). This is the most elementary form of the model [19–23], and it has widespread applications for LES of a variety of reactive flows. Some examples are in Refs. [24–48]; see Ref. [1] for a recent review. In almost all of these contributions, the FDF is considered for flows at low compressibility levels. As such, the effects of pressure fluctuations in the energy transport is negligible, and the latter is governed by a scalar equation similar to that for the composition. Some corrections to account for the effects of pressure in LES of compressible flows have been attempted [49–51].

The objective of the present work is to extend the FDF methodology to a self-contained manner for flows with both low and high levels of compressibility. This is facilitated by SGS modeling of all of the pertinent transport variables of compressible flows, as required for a stand-alone description. The central part of the formulation is the pressure term, which provides the coupling between hydrodynamics and thermochemistry. This term is coupled with the internal energy, the fluid velocity, and the composition field. Consistent with established terminology, the resulting model is termed PEVC-FMDF. With the formal definition of PEVC-FMDF, the mathematical framework for
its implementation in LES is established. A transport equation is developed for the PEVC-FMDF in which the effect of the SGS convection appears in closed form. The unclosed terms are modeled via a set of stochastic differential equations (SDEs). Since the FDF is a single-point descriptor, all of the multipoint statistics are also modeled externally. A Lagrangian Monte Carlo procedure is developed and implemented for the numerical solution of these SDEs. Simulations are conducted of a turbulent shear flow with variable levels of compressibility. The consistency and the overall capability of the closure is assessed via comparison with DNS data.

II. FORMULATION

For the mathematical description of compressible flows involving \( N_s \) species, the primary transport variables are the density \( \rho(\mathbf{x},t) \), velocity vector \( \mathbf{u}_i(\mathbf{x},t) \) \((i=1,2,3)\), pressure \( p(\mathbf{x},t) \), temperature \( T(\mathbf{x},t) \), internal energy \( e(\mathbf{x},t) \), and species mass fractions \( \phi_\alpha(\mathbf{x},t) \) \((\alpha=1,\ldots,N_s)\). The equations which govern the transport of the above variables in space \( (x_i) \) and time \( (t) \) are the continuity, conservation of momentum, internal energy, and species mass fractions:

\[
\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_j}{\partial x_j} = 0, \tag{1a}
\]

\[
\frac{\partial \rho u_i}{\partial t} + \frac{\partial \rho u_i u_j}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j}, \tag{1b}
\]

\[
\frac{\partial \rho e}{\partial t} + \frac{\partial \rho e u_j}{\partial x_j} = -\frac{\partial q_j}{\partial x_j} + \sigma_{ij} \frac{\partial u_i}{\partial x_j}, \tag{1c}
\]

\[
\frac{\partial \rho \phi_\alpha}{\partial t} + \frac{\partial \rho \phi_\alpha u_j}{\partial x_j} = -\frac{\partial J^\alpha_j}{\partial x_j}, \quad \alpha = 1,2,\ldots,N_s. \tag{1d}
\]

For a Newtonian fluid, the viscous stress tensor \( \tau_{ij} \), the heat flux \( q_j \), the species \( \alpha \) diffusive mass flux vector \( J^\alpha_j \), and \( \sigma_{ij} \) tensor are represented by

\[
\tau_{ij} = \mu \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} - \frac{2}{3} \frac{\partial u_k}{\partial x_k} \delta_{ij} \right), \quad q_j = -\lambda \frac{\partial T}{\partial x_j}, \quad J^\alpha_j = -\rho \Gamma_\alpha \frac{\partial \phi_\alpha}{\partial x_j}, \quad \sigma_{ij} = \tau_{ij} - p \delta_{ij}, \tag{2}
\]

where \( \mu \) is the fluid dynamic viscosity, \( \lambda \) is the thermal conductivity, and \( \Gamma_\alpha \) denotes the mass diffusion coefficient. To put the equations in a compact form, and for compatibility with the simulation results presented in the next section, we assume a perfect gas with the specific heat ratio \( \gamma = c_p/c_v \) and internal energy \( de = c_v dT \), where \( c_p \) and \( c_v \) denote the specific heats at constant pressure and constant volume, respectively, and are assumed to be constants. The diffusion coefficients are the same for all of the species \( (\Gamma_\alpha = \Gamma_\beta = \Gamma) \), and we assume \( \mu = \rho \Gamma \) and \( c_v \mu = \lambda \), i.e., unity Schmidt (\( Sc = \frac{\mu}{\rho \Gamma} \)) and Prandtl (\( Pr = \frac{c_v \mu}{\lambda} \)) numbers. The viscosity and molecular diffusion coefficients can, in general, be temperature dependent but in this initial study, they are assumed to be constants. In reactive flows, molecular processes and thermodynamics are much more complicated than portrayed here. These are not our primary concern here, so the simple model is adopted with justifications and caveats given in Refs. [52–54]. With these assumptions, the equation of state is expressed as

\[
p = \rho R^0 T/M = \rho RT = (\gamma - 1) \rho e, \tag{3}
\]

where \( R^0 \) and \( R \) are the universal and mixture gas constants, and \( M \) is the molecular weight for the mixture. Therefore, the pressure is governed by [55]

\[
\frac{\partial p}{\partial t} + \frac{\partial p u_j}{\partial x_j} = -(\gamma - 1) \frac{\partial q_j}{\partial x_j} + (\gamma - 1) \sigma_{ij} \frac{\partial u_i}{\partial x_j}. \tag{4}
\]
Large-eddy simulation involves the spatial filtering operation \([56–60]\)

\[
\langle Q(x,t) \rangle_{\ell} = \int_{-\infty}^{+\infty} Q(x',t) G_{\Delta_1}(x',x) d'x,
\]

(5)

where \(G_{\Delta_1}(x',x)\) denotes a filter function, and \(\langle Q(x,t) \rangle_{\ell}\) is the filtered value of the transport variable \(Q(x,t)\). In this definition, the subscript “\(\ell\)” for the filter function indicates that \(\langle Q(x,t) \rangle_{\ell}\) is the first-level filter value of variable \(Q(x,t)\). \([61]\). In variable-density flows, it is convenient to use the Favre-filtered quantity \(\langle Q(x,t) \rangle_{L} = \langle \rho Q \rangle_{\ell} / \langle \rho \rangle_{\ell}\). We consider a filter function that is spatially and temporally invariant and localized, thus \(G_{\Delta_1}(x',x) = G_{\Delta_1}(x' - x)\) with the properties \(G_{\Delta_1}(x) \geq 0\), \(\int_{-\infty}^{+\infty} G_{\Delta_1}(x) dx = 1\). Also, the second-level spatial filtering operation is defined as

\[
\langle \langle Q(x,t) \rangle_{\ell} \rangle_{\ell_2} = \int_{-\infty}^{+\infty} \langle Q(x',t) \rangle_{\ell} G_{\Delta_2}(x',x) dx',
\]

(6)

where \(G_{\Delta_2}(x',x)\) denotes a secondary filter function. Similar to the first-level filtering operation, \(\langle \langle Q(x,t) \rangle_{L} \rangle_{L_2} = \langle \langle \rho Q \rangle_{\ell} \rangle_{\ell_2} / \langle \langle \rho \rangle_{\ell} \rangle_{\ell_2}\).

### III. PEVC-FMDF

#### A. Exact transport equation

The PEVC-FMDF, denoted by \(P_L\), is formally defined as \([19]\)

\[
P_L(v, \psi, \theta, \eta, x; t) = \int_{-\infty}^{+\infty} \rho(x',t) \zeta(v, \psi, \theta, \eta; u(x',t), \phi(x',t), e(x',t), p(x',t)) G(x' - x) dx',
\]

(7)

where

\[
\zeta(v, \psi, \theta, \eta; u(x,t), \phi(x,t), e(x,t), p(x,t)) = \left( \prod_{i=1}^{3} \delta(u_i - u_i(t)) \right) \left( \prod_{a=1}^{\sigma=N_s} \delta(\psi_a - \phi_a(x,t)) \right) \times \delta(\theta - e(x,t)) \times \delta(\eta - p(x,t)),
\]

(8)

where \(\delta\) denotes the Dirac \(\delta\) function, and \(v, \psi, \theta, \eta\) are the velocity vector, composition vector, internal energy, and pressure in the sample space. The term \(\zeta\) is the “fine-grained” density \([53,62]\). Equation (7) defines the PEVC-FMDF as the spatially filtered value of the fine-grained density. With the condition of a positive filter kernel \([63]\), \(P_L\) has all of the properties of a mass density function (MDF) \([53]\). For further developments, it is useful to define the “conditional filtered value” of the variable \(Q(x,t)\) as

\[
\langle Q(x,t) | u(x,t) = v, \phi(x,t) = \psi, e(x,t) = \theta, p(x,t) = \eta \rangle_L \equiv \langle Q|v,\psi,\theta,\eta \rangle_L
\]

\[
= \frac{\int_{-\infty}^{+\infty} Q(x',t) \rho(x',t) \zeta(v, \psi, \theta, \eta; u(x',t), \phi(x',t), e(x',t), p(x',t)) G(x' - x) dx'}{P_L(v, \psi, \theta, \eta, x; t)}.
\]

(9)

Equation (9) implies the following:

1. For \(Q(x,t) = c\),

\[
\langle Q(x,t) | v, \psi, \theta, \eta \rangle_L = c.
\]

(10a)

i.e., the conditional mean of a constant is the constant.

2. For \(Q(x,t) \equiv \hat{Q}(u(x,t), \phi(x,t), e(x,t), p(x,t))\),

\[
\langle Q(x,t) | v, \psi, \theta, \eta \rangle_L = \hat{Q}(v, \psi, \theta, \eta),
\]

(10b)

i.e., the conditional mean of a known function of the dependent variables is simply the function evaluated based on the conditioning (sample-space) variables.
conventional LES approximation for the diffusion terms) Eqs. (1):  

\[ \partial_t \langle \rho(x,t) \rangle_L + \delta_p \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_j} = 0, \]  

(15a)  

\[ \frac{\partial \langle \rho(x,t) \rangle_L }{\partial t} + \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_j} = - \frac{\hat{\delta}_j}{\delta_p} - \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_j} - \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_i} \],  

(15b)  

\[ \frac{\partial \langle \rho(x,t) \rangle_L }{\partial t} + \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_j} = - \frac{\partial \hat{\delta}_j}{\delta_p} - \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_j} + j_{ij} \frac{\partial \langle \rho(x,t) \rangle_L }{\partial x_j} + \epsilon - \Pi_d - \langle p \rangle \frac{\partial \langle u_i \rangle_L }{\partial x_i} \],  

(15c)
SELF-CONTAINED FILTERED DENSITY FUNCTION

\[
\frac{\partial \langle \rho \rangle_{\ell}(\phi_a)_L}{\partial t} + \frac{\partial \langle \rho \rangle_{\ell}(u_j)_L(\phi_a)_L}{\partial x_j} = -\frac{\partial J^a_{\ell}}{\partial x_j} - \frac{\partial \langle \rho \rangle_{\ell} \tau_L(\phi_a,u_j)}{\partial x_j}, \tag{15d}
\]

where \( \tau_L(a,b) = \langle ab \rangle_L - \langle a \rangle_L \langle b \rangle_L \),

\[
\bar{\xi}_{ij} = \mu \left( \frac{\partial \langle u_i \rangle_L}{\partial x_j} + \frac{\partial \langle u_j \rangle_L}{\partial x_i} - \frac{2}{3} \frac{\partial (u_k)_L \delta_{ij}}{\partial x_k} \right), \quad \bar{q}_j = -\frac{1}{\gamma} \frac{\partial \langle T \rangle_L}{\partial x_j}, \quad J^a_{\ell} = -\langle \rho \rangle_{\ell} \frac{1}{\gamma} \frac{\partial \langle \phi_a \rangle_L}{\partial x_j}, \tag{16}
\]

and \( \Pi_d \) and \( \epsilon \) denote the SGS pressure dilatation and dissipation, respectively:

\[
\Pi_d = \left[ P \frac{\partial u_i}{\partial x_i} \right]_{\ell} - \langle P \rangle_{\ell} \frac{\partial \langle u_i \rangle_{\ell}}{\partial x_i}, \quad \epsilon = \left( \tau_{ij} \frac{\partial u_i}{\partial x_j} \right)_{\ell} - \bar{\xi}_{ij} \frac{\partial \langle u_i \rangle_{L}}{\partial x_j}. \tag{17}
\]

B. Modeled transport equation

To develop the model for the PEVC-FMDF, the notion of stochastic particles [56] is used. This is via development of SDEs governing the FDF transport variables: \( U_i^+, \phi_a^+, E^+, \) and \( P^+ \). The internal energy is modeled according to the first law of thermodynamics:

\[
dE^+ = \left( -C_e \Omega [E^+ - \langle e \rangle_L] + \frac{E^+ (\gamma - 1)}{P^+} \epsilon \right) dt - P^+ d\xi^+, \tag{18}
\]

where \( C_e \) is the model constant, \( \Omega \) denotes the SGS mixing frequency, and \( \xi^+ = 1/\rho^+ \) is the specific volume relating \( E^+ \) and \( P^+ \) through the equation of state. In the context of single-point formulation, both of these variables need closures. In the absence of better alternatives, the simple models suggested in the previous work [9] are adopted:

\[
\epsilon = \langle \rho \rangle_{\ell} C_e k^{3/2} / \Delta_L, \quad \Omega = \epsilon / \langle \rho \rangle_{\ell}, \tag{19}
\]

here \( C_e \) is the model constant, \( \Delta_L \) is the LES filter size, and \( k = 1/2 \tau_L(u_i,u_i) \) is the SGS kinetic energy. The pressure SDE is written in the general form

\[
dP^+ = P^+(Adt + BdW_p), \tag{20}
\]

where \( W_p(t) \) denotes the Wiener process [64]. With this, the energy SDE takes the form

\[
dE^+ = \left[ -\frac{C_e \Omega}{\gamma} (E^+ - \langle e \rangle_L) + \frac{\gamma - 1}{\gamma} P^+ \epsilon + \frac{\gamma - 1}{\gamma} E^+ \left( A - \frac{B^2}{\gamma} \right) \right] dt + \frac{\gamma - 1}{\gamma} E^+ BdW_p. \tag{21}
\]

The coefficients \( A \) and \( B \) are determined so that the exact and modeled transport equations for energy are identical, and the filtered specific volume is consistently determined by the FDF and the equation of state. There are different combinations of \( A \) and \( B \) that satisfy these constraints. To ensure realizability, we select the model [65,66]

\[
A = \frac{\epsilon (\gamma - 1)}{P^+} - \gamma \frac{\partial \langle u_j \rangle_{\ell}}{\partial x_j} + \chi_p (\gamma - 1)(P^+ - \langle P \rangle_{\ell}) + \gamma \frac{\partial}{\partial x_j} \left[ \frac{1}{\langle \rho \rangle_{\ell}} \right] \frac{\partial}{\partial x_j} \left[ \frac{1}{\langle \rho \rangle_{\ell}} \right], \tag{22}
\]

\[
B = 0, \tag{23}
\]

with

\[
\chi_p = \frac{\gamma}{(\gamma - 1) A(p,p)} \left[ \tau_{ij} \frac{\partial \langle u_i \rangle_L}{\partial x_j} - F_d - \langle P \rangle_{\ell} \frac{\partial}{\partial x_j} \left[ \frac{1}{\langle \rho \rangle_{\ell}} \right] \right]. \tag{24}
\]

where \( F_d \) is the general form of the model for the pressure dilatation based on known SGS statistics. For modeling of the other variables, we follow Refs. [12,18,22,67,68] and use the simplified Langevin
ensemble of MC particles, each carrying the information pertaining to its position
and velocity. The FDF is represented by an ensemble of SLM and linear mean-square estimation (LMSE) model [69]:

\[ dX_i^+ = U_i^+ dt + \sqrt{\frac{2\mu}{\langle \rho \rangle_\ell}} dW_i, \]  
\[ dU_i^+ = -\frac{1}{\langle \rho \rangle_\ell} \frac{\partial \langle p \rangle_\ell}{\partial x_i} dt + \frac{2}{\langle \rho \rangle_\ell} \frac{\partial}{\partial x_j} \left( \mu \frac{\partial \langle u_i \rangle_L}{\partial x_j} \right) dt + \frac{1}{\langle \rho \rangle_\ell} \frac{\partial}{\partial x_j} \left( \mu \frac{\partial \langle u_j \rangle_L}{\partial x_i} \right) dt \]

\[ -\frac{2}{3} \frac{1}{\langle \rho \rangle_\ell} \frac{\partial}{\partial x_i} \left( \mu \frac{\partial \langle u_j \rangle_L}{\partial x_j} \right) dt + G_{ij}(U_j^+ - \langle u_j \rangle_L) dt + \sqrt{\frac{2\mu}{\langle \rho \rangle_\ell}} \frac{\partial \langle u_i \rangle_L}{\partial x_j} dW_j, \]  
\[ d\phi_a^+ = -C_\phi \Omega (\phi_a^+ - \langle \phi_a \rangle_L) dt, \]

where \( W, W' \) denote the Wiener process in the physical and the velocity spaces, respectively, and

\[ G_{ij} = \left[ -\frac{\Pi_d}{2k\langle \rho \rangle_\ell} - \Omega \left( \frac{1}{2} + \frac{3}{4} C_0 \right) \right] \delta_{ij}, \]

in which we employ the model

\[ \Pi_d = C_\pi \left( \langle \langle p \rangle_\ell \frac{\partial \langle u_i \rangle_L}{\partial x_j} \rangle_{\ell_2} - \langle \langle p \rangle_\ell \rangle_{\ell_1} \frac{\partial \langle u_i \rangle_L}{\partial x_j} \right). \]

The parameters \( C_0, C_\phi, \) and \( C_\pi \) are the model constants and needed to be specified [11,70]. The Fokker-Planck equation [71], governing the joint probability density function of the SGS transport parameters, is

\[ \frac{\partial F_L}{\partial t} + \frac{\partial v_i F_L}{\partial x_i} = \frac{1}{\langle \rho \rangle_\ell} \frac{\partial \langle p \rangle_\ell}{\partial x_i} \frac{\partial F_L}{\partial v_i} - \frac{2}{\langle \rho \rangle_\ell} \frac{\partial}{\partial x_j} \left( \mu \frac{\partial \langle u_i \rangle_L}{\partial x_j} \right) \frac{\partial F_L}{\partial v_i} - \frac{1}{\langle \rho \rangle_\ell} \frac{\partial}{\partial x_j} \left( \mu \frac{\partial \langle u_j \rangle_L}{\partial x_i} \right) \frac{\partial F_L}{\partial v_i} \]

\[ + \frac{2}{3} \frac{1}{\langle \rho \rangle_\ell} \frac{\partial}{\partial x_i} \left( \mu \frac{\partial \langle u_j \rangle_L}{\partial x_j} \right) \frac{\partial F_L}{\partial v_i} - \frac{\partial}{\partial x_j} \left( \mu \frac{\partial \langle u_j \rangle_L}{\partial x_j} \right) \frac{\partial F_L}{\partial v_i} + \frac{\partial}{\partial x_i} \left( \frac{2\mu}{\langle \rho \rangle_\ell} \frac{\partial \langle u_j \rangle_L}{\partial x_j} \frac{\partial F_L}{\partial v_i} + \mu \frac{\partial \langle u_k \rangle_L}{\partial x_j} \frac{\partial \langle u_j \rangle_L}{\partial v_i} \right) \frac{\partial F_L}{\partial v_i} \]

\[ + \frac{1}{2} \frac{C_0}{\langle \rho \rangle_\ell} \frac{\partial}{\partial v_i} \left( \frac{\partial F_L}{\langle \rho \rangle_\ell} \right) \frac{\partial F_L}{\partial v_i} + C_\phi \Omega \frac{\partial (\langle \psi_a \rangle_L F_L)}{\partial \psi_a} + C_\pi \Omega \frac{\partial ((\theta - \langle \epsilon \rangle_L) F_L)}{\partial \theta} - \frac{\gamma - 1}{\gamma} \frac{\partial (\theta A F_L)}{\partial \theta} \]

\[ - \frac{1}{\gamma} \frac{\partial (\theta B F_L)}{\partial \theta} + \frac{1}{2} \frac{\partial (\theta B^2 F_L)}{\partial \theta} - \frac{\partial (\eta A F_L)}{\partial \eta} + \frac{1}{2} \frac{\partial (\eta B^2 F_L)}{\partial \eta} \]

\[ + \frac{1}{2} \frac{\partial (\theta B^2 F_L)}{\partial \eta \partial \eta} \] (28)

The transport equations for the first-order moments are obtained by integration of Eq. (28) according to Eqs. (10).

IV. NUMERICAL SOLUTION

The modeled PEVC-FMDF transport equation is solved by a hybrid finite-difference (FD)–Monte Carlo (MC) method, similar to those in previous works [3,72]. The FDF is represented by an ensemble of MC particles, each carrying the information pertaining to its position \( X^+ \), velocity \( U^+ \),

094603-6
FIG. 1. Scatter plots of (a) $\langle u \rangle_L$, (b) $\langle v \rangle_L$, (c) $\langle e \rangle_L$, and (d) $\langle \phi \rangle_L$, with $Ma = 0.6$ and $s = 2$ at $t = 45$. $r$ denotes the correlation coefficient.

Composition $\phi^+$, energy $E^+$, and pressure $P^+$. We define the $Z^+(t)$, a $8 + N_s$ vector, as

$$Z^+(t) = [X^+(t), U^+(t), \phi^+(t), E^+(t), P^+(t)],$$

which evolves by

$$dZ^+ = D(Z^+)dt + B(Z^+)dW,$$

where $W$ is the Wiener-Levy vector, and the matrices $D$ and $B$ can be identified from Eqs. (18), (20), and (25). The vector $Z$ is updated via the Euler-Maruyama discretization [73],

$$Z^+(t_{k+1}) = Z^+(t_k) + D(Z^+(t_k))\Delta t + B(Z^+(t_k))\Delta t^{1/2}\zeta_k,$$

where $\zeta_k$ is an independent standardized Gaussian random variable at time $t_k$ and $\Delta t$ is the time step. This scheme preserves the Markovian character of the diffusion processes and the Itô-Gikhman character of the SDEs [74].
The computational domain is discretized on equally spaced FD grid points. These are used to identify the regions where the statistical information are to be obtained and to perform complementary LES solely by FD discretization. The latter is referred to as LES-FD and is useful for assessing the consistency of the MC solver. In this solver, the statistical information is obtained by considering an ensemble of $N_E$ MC particles residing within a cubic domain of side $\Delta_E$ centered around each of the FD points. For reliable statistics with minimal numerical dispersion, it is desired to minimize the size of the ensemble domain and maximize the number of the MC particles [53]. In this way,

\[
\langle a \rangle_E \equiv \frac{\sum_{n \in \Delta_E} w^{(n)} a^{(n)}}{\sum_{n \in \Delta_E} w^{(n)}} \xrightarrow{N_E \to \infty \atop \Delta_E \to 0} \langle a \rangle_L,
\]

\[
\tau_E(a, b) \equiv \left( \frac{\sum_{n \in \Delta_E} w^{(n)} a^{(n)} b^{(n)}}{\sum_{n \in \Delta_E} w^{(n)}} \right) - \langle a \rangle_E \langle b \rangle_E \xrightarrow{N_E \to \infty \atop \Delta_E \to 0} \tau_L(a, b),
\]

FIG. 2. Contour surfaces of the instantaneous $\langle \phi \rangle_L$ field. (a) $Ma = 0.2$, $s = 2$ and $t = 50$. (b) $Ma = 1.2$, $s = 2$ and $t = 75$. 
where $w^{(n)}$ is the weight of the $n^{th}$ MC particle and $a^{(n)}$ denotes the information carried by that particle pertaining to transport variable $a$. The LES-FD solver is based on the second-order predictor-corrector scheme. All of the FD operations are conducted on fixed grid points. The transfer of information from these points to the MC particles is via a trilinear interpolation. The transfer of information from the particles to the grid points is by means of ensemble averaging.
The transport equations to be solved by the LES-FD include unclosed second-order moments which are obtained from the MC. The LES-FD also determines the filtered values of the transport variables. This redundancy is useful in monitoring the accuracy and consistency of the FDF results [18,72,75].

V. RESULTS

A. Flow and numerical specifications

Simulations are conducted of a three-dimensional (3D) temporally developing mixing layer involving the transport of a passive scalar. The temporal layer consists of two parallel streams traveling in opposite directions with the same speed [20,76–78]. The LES predictions are compared with direct numerical simulation (DNS) data of the same layer. In this layer, \( x, y, \) and \( z \) denote the streamwise, the cross-stream, and the spanwise directions, respectively. The velocity components along these directions are denoted, in order, by \( u, v, \) and \( w \). The transport variables are normalized with respect to the half initial vorticity thickness, \( \delta_v = \frac{\delta v}{\langle u \rangle_L \lambda u} \). Here, \( \delta_v = \frac{\Delta U}{\langle u \rangle_L \lambda u} \), where \( \langle u \rangle_L \lambda u \) is the Reynolds-averaged value of the filtered streamwise velocity and \( \Delta U \) is the velocity difference across the layer. The length \( L_v \) is specified such that \( L_v = 2^{N_v} \lambda u \), where \( N_v \) is the desired number of successive vortex pairings and \( \lambda u \) is the wavelength of the most unstable mode corresponding to the mean streamwise velocity profile imposed at the initial time. The normalized filtered streamwise velocity, the scalar composition, and the temperature are initialized with a hyperbolic tangent profiles with \( \langle u \rangle_L = 1, \langle \phi \rangle_L = 1 \) on the top stream, and \( \langle u \rangle_L = -1, \langle \phi \rangle_L = 0 \) on the bottom stream. With

a constant initial pressure, the parameter “$s$” denotes the initial density ratio across the layer; the values $s = 1, 2, 4$ are considered. The reference velocity is $U_r = \Delta U/2$. The Reynolds number is set ($Re = \frac{U_r L_r}{\nu} = 50$, and the Mach numbers ($Ma = \frac{U_r}{\sqrt{\gamma RT_r}}$) values of 0.2, 0.6, and 1.2 are considered. The number of test cases and the magnitude of the Reynolds number, as considered, are based on the amount of available computational resources.

The three-dimensional (3D) field is initialized in a procedure somewhat similar to that in Ref. [78]. The formation of the large-scale structures are expedited through eigenfunction-based initial perturbations. This includes 2D and 3D perturbations with a random phase shift between the modes. This yields the formation of two successive vortex pairings and strong three-dimensionality. Periodic boundary conditions are imposed in the homogeneous directions (x and z), and characteristic...

boundary conditions [79] are employed in the cross-stream direction. Simulations are conducted on a box, $0 \leq x \leq L$, $-\frac{3L}{2} \leq y \leq \frac{3L}{2}$, $0 \leq z \leq L$, where $L = L_v/L_r$. The layer is discretized with nearly equally spaced grid points ($\Delta y \cong \Delta x = \Delta z$) with the number of grid points $193 \times 577 \times 193$ for DNS and $65 \times 193 \times 65$ for LES. Some lower resolution LES $33 \times 97 \times 33$ were also conducted for production runs. The resolution in LES was determined in such a way that a reasonable amount (75–85%) of turbulent energy is captured by the resolved scale. To filter the DNS data, a top-hat

function is used with $\Delta_L = 2\Delta$, where $\Delta = (\Delta_x\Delta_y\Delta_z)^{1/3}$. The LES filter sizes are $\Delta_1 = \Delta_L$ and $\Delta_2 = 2\Delta_L$. No attempt is made to investigate the sensitivity of the results to the filter function [63] or the size of the filter [80–82].

The MC particles are initially distributed uniformly within the domain in a random fashion. The particle weights, $w(n)$, are set according to filtered fluid density at the initial time. The initial number of particles per grid point (NPG) is 80, and the ensemble domain size ($\Delta_E$) is set equal to the grid spacing. The effects of both of these parameters have been assessed in previous works [11,18,22,23]. All results are analyzed both instantaneously and statistically. In the former, the instantaneous scatter plots of the variables of interest are analyzed. In the latter, the Reynolds-averaged statistics constructed from the instantaneous data are considered. These are constructed by spatial averaging over homogeneous directions. All Reynolds-averaged results are denoted by an overbar. No attempt is made to determine the optimum magnitudes of the model constants. The values as suggested in the literature are adopted for $C_0 = 2.1$ and $C_\phi = C_\epsilon = 1$ [11,83]. The values of $C_\Pi = 1$ and $C_{\Pi} = 1.4$ were chosen based on comparison with DNS data for one set of the simulations and were used in all the subsequent ones.

**B. Consistency and validity assessments**

To demonstrate consistency, the redundancy of the repeated fields is portrayed by scatter plots of the instantaneous values. The accuracy of the LES-FD is relatively well-established (at least for the first-order filtered quantities), thus the comparative assessment provides a good measure of the MC performance. Sample results are given in Fig. 1, and portray a reasonable consistency.

For comparison with DNS data, the resolved and the total components of the Reynolds-averaged moments are considered. The former is denoted by $R(a,b)$, with $R(a,b) = \langle (a)_L - \langle a \rangle_L \rangle \langle (b)_L - \langle b \rangle_L \rangle$, and the latter by $r(a,b)$, with $r(a,b) = (a - \bar{a})(b - \bar{b})$. In DNS, the total components are directly available, while in LES they are approximated via $r(a,b) \approx R(a,b) + \tau_L(a,b)$ [55].

Figure 2 shows the instantaneous isosurfaces of the composition field $\langle \phi \rangle_L$ obtained by PEVC-FMDF for $Ma = 0.2$ at $t = 50$ and $Ma = 1.2$ at $t = 75$. By these times, the flows have gone through
SELF-CONTAINED FILTERED DENSITY FUNCTION

FIG. 12. Cross-stream variation of some of the Reynolds-averaged components of $\tau_L$ at $t = 75$ with $Ma = 1.2$ and $s = 2$. The thick solid line denote LES predictions using PEVC-FMDF and circles show the DNS data.

pairings and exhibit strong 3D effects. This is evident by the formation of large-scale spanwise rollers with the presence of secondary structures in streamwise planes [84].

Figure 3 shows the Reynolds-averaged, filtered density, and streamwise velocity fields. The level of agreement between PEVC-FMDF and DNS is satisfactory. Similar agreements are observed for all other filtered variables. The figure is also indicative of the accurate prediction of shear layer center location by PEVC-FMDF. As the density ratio increases, the shear layer center, defined as the dividing mean streamline position (the position where $\langle u \rangle_L$ is equal to the average of the free stream velocities), is shifted further to the low-density side. As a result, the peak values of the Reynolds stresses and scalar fluxes also show a shift to the low-density side. The shift is known to be responsible for the decreased correlation between density and velocity components [85] and hence reduction in turbulent production terms. The growth rate of the later is related to the integrated turbulent production [86]. Therefore, a decrease in this production results in reduction of the layer growth rate. This is evidenced in Fig. 4, which shows the temporal evolution of the momentum thickness ($\delta_m$) [63]. As Fig. 4 shows, the shear layer growth rate reduces with increasing the density ratio, and increasing the Ma number. This is consistent with previous DNS results [20,76,87]. However, the spreading rates as predicted by the FDF are somewhat smaller than those by DNS. This was also observed in previous FDF simulations [9].

Several components of the resolved second-order resolved and SGS moments are presented in Figs. 5, 6, 8, 9, 11, and 12. As observed, the PEVC-FMDF yields reasonable predictions. As a result, the total components also yield very good agreements with DNS data as shown in Figs. 7, 10, and 13.

VI. SUMMARY AND CONCLUSIONS

The filtered density function (FDF) has proven to be a very effective subgrid scale closure for large-eddy simulation of turbulent reactive flows [2,3]. In all previous works, the FDF were considered for selected transport variables; the closure for other variables was provided by other means. The objective of the present work is to develop the FDF in a self-contained manner, accounting for SGS statistics of all of the transport variables. For this purpose, the pressure-energy-velocity-composition filtered mass density function (PEVC-FMDF) is developed. The exact transport equation governing

the evolution of this FDF is derived. It is shown that the effect of SGS convection appears in closed form. The unclosed terms are modeled in a fashion similar to that in probability density function methods. The capability of the PEVC-FMDF is demonstrated by conducting LES of a temporally developing mixing layer. The performance of the model as appraised by comparisons with DNS data is encouraging.

Future work must consider other kernels of the SLM coupled with more comprehensive SGS pressure-strain correlations, e.g., Refs. [88]. The same goes for developments of more sophisticated models for the terms requiring multipoint statistical information: SGS dissipation, dilatation, and frequency. Extension to LES of reactive flows is straightforward if reliable kinetics models are provided. Future applications to a broader class of flows with escalated degrees of complexity are also recommended. With these extension, LES of practical flows with this self-contained FDF becomes possible, as is currently the case with scalar FDF [39].
